Management of Large Radicular Cyst by Conservative Surgical Approach: A Case Report

NILESH S. KADAM1, IDA DE NORONHA DE ATAIDE2, PHANI RAGHAVA3, MARINA FERNANDES4, RUBY HEDE5

ABSTRACT
Radicular cysts are the most common cystic lesions which affect the jaw. They are most common among all the jaw cysts and comprise about 52% to 68% of the entire cysts which affect the human jaw. They are generally symptomless and are diagnosed during routine radiologic investigations. The treatment of radicular cysts includes conventional nonsurgical root canal therapy when lesion is localized or surgical treatment like enucleation, marsupialization or decompression when lesion is large. This case report presents the successful surgical management of a large infected radicular cyst which was associated with maxillary central incisor with open apex.

CASE REPORT
A 38-year-old male patient reported to the Department of Conservative Dentistry, Goa Dental College and Hospital, Goa, with chief complaint of swelling in the upper front region of jaw, which had occurred 1 year back. Patient gave history of trauma in upper anterior teeth, which had occurred more than 25 years back. Patient had visited a private clinic 1 year prior for a similar complaint. Root canal opening was done with 11 and 21.

Intraoral clinical examination revealed a round to oval swelling which was located over labial mucosa of maxillary anterior region in association with 21,11,12 and 13. Swelling was soft, localized, fluctuant, inflamed and nontender. Spontaneous pus discharge was seen from gingival sulcus. Ellis class IV fractures of 11 and 22 with severe discoloration were also seen.

Electric and thermal pulp vitality testing showed negative responses in 21,11,12, and 13, while 22 showed a delayed response. All teeth were non-tender to percussion test. An IOPA was taken, which revealed a large unilocular radiolucent lesion which involved periradicular regions of 21,11,12 and 13 respectively. Also, incomplete development of root, which led to open apex, was seen with 21. True occlusal X-ray and OPG showed unilocular radiolucency with sclerotic borders and there was no cortical expansion.

Patient was subjected to CT scan for further exploration of the finding, to check for proximity or any involvement of lesion with nasal floor, since lesion was extensive. CT showed that the nasal floor was intact and the radiolucency was seen in relation with 21 in sagittal and coronal planes. Based on these, a 3D construction image was plotted. The dimension of the lesion was measured by using measurement scale which was around 12x2.5x2.5 mm. A fine needle aspiration of the swelling was done and it was sent for protein estimation, which was 6.6 g/dl.

From the history, clinical examination and investigation, a provisional diagnosis of infected radicular cyst in 22 was made.

Treatment plan was formulated and after explaining it to the patient, his informed consent was taken. Root canal opening with 11,12,13,21 and 22 was done under rubber dam application. Pus discharge was...
DISCUSSION

The term, ‘cyst’ is derived from the Greek word, ‘Kystis’, meaning, ‘sac or bladder’ [1]. Cyst is defined as a pathological cavity that is usually lined by epithelium and which has a centrifugal, expansive mode of growth [2].

Radicular cysts are the most common cystic lesions which affect the jaw. They are most common of all the jaw cysts and comprise about 52% to 68% of all the cysts which affect the human jaw [3,4]. They arise from epithelial remnants which are stimulated to proliferate, by an inflammatory process which originates from pulpal necrosis of a non-vital tooth. The natural history begins with a non-vital tooth which remains in situ, long enough to develop chronic periapical pathosis [5]. They are most commonly found at the apices of the involved teeth. However, they may also be found on the lateral aspects of the roots in relation to lateral accessory root canals [6]. They are symptomless and are diagnosed during routine radiologic investigations. The treatment for radicular cysts includes conventional nonsurgical root canal therapy when lesion is localized or surgical treatment like enucleation, marsupialization or decompensation when lesion is large [7].

Radicular cysts generally originate after trauma or dental caries. Dental caries cause inflammation of the pulp cavity, leading to pulp death and infection. The infection spreads to the periapical region and causes an inflammatory response, leading to the formation of a radicular cyst. The cystic lesion then expands and may cause symptoms such as pain, swelling, and loosening of the tooth. Surgical treatment is necessary to remove the cystic tissue and to treat the underlying cause, such as a non-vital tooth or a tooth with a perforated root.

The treatment for radicular cysts includes conventional nonsurgical root canal therapy when lesion is localized or surgical treatment like enucleation, marsupialization or decompensation when lesion is large [7]. Radiographic evaluation is crucial in the diagnosis and management of radicular cysts. Radiographic findings include a well-circumscribed radiolucency, which may be associated with a non-vital tooth.

The histopathology report confirmed the provisional diagnosis of an infected radicular cyst [Table/Fig-5a,5b]. Post-operative instructions were given to the patient and patient was kept on antibiotics and analgesics. Currently, the patient is asymptomatic and he is under follow-up since 1 year [Table/Fig-6a,6b]. Follow-up radiograph showed appreciable healing.
Infiltration being present [Table/Fig-5a,5b]. Keratinized, stratified squamous epithelium with mixed inflammatory cells is the typical tissue found in radicular cysts.[9] In the current case, there was cortical perforation and adjacent teeth in relation to the cyst were non-vital, which is not common. It has been stated that as the cyst enlarges, adjacent teeth can become non-vital[10].

The use of root canal dressings between sessions in root canal treatment of teeth with chronic periapical lesions is important, for reducing bacteria which are unreachable by instruments or irrigation solutions, such as dentinal tubules and ramifications[11]. Takahashi et al., after analyzing the pH and the concentration of calcium ions in the periapical area, concluded that at least 2 weeks were necessary for calcium hydroxide bactericidal activity[12]. In the current case, calcium hydroxide intracanal medicament was used. When the canal is wide and walls are parallel, the tapered shape of GP will not fit adequately. In such cases, it is necessary to roll three or more GP cones together on glass slab, in order to make a thick GP cone of even diameter[13]. In the current case, tooth 21 presented with wide canals with open apex. It was successfully managed by roll cone technique obturation.

Due to the large size of the lesion, conservative surgical approach was planned. Conservative approach involves the removal of the infected tissues as compared to procedures like En bloc resection, which involves removal of the normal structure along with diseased tissue. The surgical approach to cystic lesions of the jaws is either marsupialization or enucleation. The treatment of choice is dependent on the size and localization of the lesion, the bone integrity of the cystic wall and its proximity to vital structures[14]. MTA is widely used as a root end filling material[15,16]. MTA has been favoured due to its higher biocompatibility and sealing ability compared to other materials. Shahi S. Comparison of the sealing ability of mineral trioxide aggregate and Portland cement used as root-end filling materials. Int J Pediatr Otorhinolaryngol. 2011;53:517-22.

Comparison of the sealing ability of mineral trioxide aggregate and Portland cement used as root-end filling materials. Int J Pediatr Otorhinolaryngol. 2011;53:517-22.

In the current case, the lesion was enucleated along with curettage, followed by apicectomy and placement of MTA as root end filling material.

Post-surgical period was uneventful. The histopathological features of the submitted lesion were consistent with the clinical diagnosis of infected radicular cyst. The cystic cavity was lined by non-keratinized, stratified squamous epithelium with mixed inflammatory infiltration being present [Table/Fig-5a,5b].

Intracoronal bleaching, followed by composite restoration, was planned for the patient. But patient was not interested in the restorative phase of the treatment due to economical reasons.

Healing of the periapical area has not yet been completed, due to large area of destruction. Currently, patient is asymptomatic and he has been kept under observation.

CONCLUSION
The current concept in management of periapical cysts is using nonsurgical means. However, depending on size and extent of lesion, surgical management might be necessary, for achieving success. Current case was managed successfully by performing endodontic therapy with thorough irrigation, cleaning and shaping and obturation of the canal space, followed by surgery.
